#### Abstract

The apricot (Prunus armeniaca L.) is one of the most appreciated species of fruit trees in Romania, due to its high-quality fruits, which can be valued at a high price. In recent years we have been experiencing very low temperatures during spring time, with severe frosts and hoarfrosts that negatively influence the production of this species. The study was carried out at Research Station for Fruit Growing Constanța from 2018 to 2022 in a plot of apricots in the period of maximum fructification on three varieties with different fruit ripening periods - early, middle and late, in order to establish a connection between the times of application of pruning and the number of fruit buds differentiated on perennial and annual branches. In the apricot cultivars studied, the obtained results indicate that pruning at the beginning of the dormancy period (November) is beneficial within the years without climatic accidents, obtaining yields of $\mathbf{2 5} \mathbf{t} / \mathrm{ha}$.

Cuvinte cheie: soiuri, tăieri, producție, greutate fruct.
Key words: cultivars, pruning, yields, fruit weight.

## 1. Introduction

The apricot finds optimal growing and fruiting conditions in the South-Eastern part of Romania, where it provides important productions with a high selling price. Consumers appreciate the quality of the fruit, the special flavor, the fineness of the orange flesh and the fact that they can be eaten fresh from the first decade of June until the second decade of August. Apricots can be used as compote, jam, comfiture or candied, etc. (Cociu, 1993; Bălan, 2008). Current climatic conditions, characterized by dry summers, winters with predominantly positive temperatures and springs with late frosts and returning mists, require a reorientation of certain technological sequences in apricot growing, including tree pruning. Thinning and fruiting pruning in apricot considerably improves branch regeneration and reduces crown size and height, thus forcing the fruit to remain close to the main skeleton branches (Demirtas et al., 2010; Szklarz et al., 2011). Green pruning of apricot (Ghiță and Drăgănescu, 2008) results in a much more vigorous growth of greedy shoots, which still requires a land intervention and considerable effort during the fruit harvesting season as well as during dormancy. How to cut the apricot trees: remove most of the greedy shoots that form an umbrella at the top of the crown that keeps out light and air. Depending on the vigor of the tree, choose between $4-6$ greedy shoots which are shortened to $60-80 \mathrm{~cm}$ and which will be garnished with fruit buds. Remove dry, diseased and mechanically damaged branches. Two- to three-year-old half-islet branches are shortened by a third, above a well-developed branch and in a position that favors the resumption of growth and fruiting. Branches older than four years are removed and replaced by new annual branches in their vicinity.

## 2. Material and methods

The study was carried out at Research Station for Fruit Growing (RSFG) Constanța during 20182022 period, in an apricot lot planted in 2011, in its peak fruiting period. Three varieties with different fruit ripening periods -early ('Elmar' cv.), middle ('Mamaia' cv.) and late ('Sulmona' cv.) were followed. The rootstock used for grafting is 'Constanta 14'. Planting distance is $4 \mathrm{~m} / 4 \mathrm{~m}$ and tree density is 625 trees $/ \mathrm{ha}$. Trees are trained as improved pot; each variant/timing of pruning was carried out on a number of 15 trees linearly arranged as follows: after fruit harvesting (V1), when entering dormancy in November (V2), when entering vegetation in March (V3).

The study aimed to establish a link between the timing of pruning and the number of differentiated fruiting shoots on multiannual and annual branches, the influence on fruit production and fruit quality under current climate change.

The following observations and determinations were made:

- Taking into account the variety and the time of pruning application, flowers were counted at different tree heights ( $50-120 \mathrm{~cm} ; 120-190 \mathrm{~cm} ; 190-260 \mathrm{~cm}$ ).
- Fruit yield was assessed by weighing the fruit from each tree in the experiment by variants and average yields were calculated for the years of the study (2018-2022).
- Percentage of stone was calculated and determinations of average dry matter content (\%) and acidity (\% malic acid) were made.

SPSS Statistics 29.0.1.0 software was used for statistical calculation. Climatic data were monitored using the IMT300 weather station at the RSFG Constanța.

## 3. Results and discussions

## Climate data recorded at SCDP Constanta during 2018-2022

In apricot, the onset and progression of the fruiting phenophase is conditioned by the emergence from dormancy, which can occur in early spring, when after a period of $7-10$ days temperatures of 5-6 ${ }^{\circ} \mathrm{C}$ are recorded; in the white button phenophase it resists up to $-4.4^{\circ} \mathrm{C}$, and apricot flowers resist up to -2.2 ${ }^{\circ} \mathrm{C}$, the bound fruits are destroyed at a temperature of $-1.0^{\circ} \mathrm{C}$. Climate data for the period January-April 2018-2022 are shown in table 1. Temperature ranges between $29.9^{\circ} \mathrm{C}$ (April, 2019) and $32.4^{\circ} \mathrm{C}$ (March, 2022), but also late fogs (April 2019, March and April 2021) were recorded, which influenced fruit production. With climate change, lower yields were recorded in early varieties of apricot due to return frosts and late mists in March and April.

## Influence of the timing of pruning on fruit buds and fruit production

From the study in apricot, it was found that fruit bud differentiation also depends on the time of pruning, Table 2. In all varieties studied, most flowers were counted in the variant of applying pruning at the trees' dormant entry (November), because, by removing greedy shoots, apricot uses the nutrient resources for the carefully preserved multiannual fruiting branches following thinning and fruiting pruning.

The presence of flowering buds in the crown is different in all the varieties of apricot studied, most flowers were counted, also in the variant of applying cuttings in the resting period (November) in the upper part of the crown, at the height of 190-260 cm: 'Elmar' and 'Sulmona' cvs. were noted with percentages of $58 \%$ and $62 \%$ respectively, and in the lower part of $16 \%-17 \%$. The trees fruited more in the upper part of the crown due to the occurrence of the polarity process, but also due to frosts and low temperatures in certain periods which are more intense near the ground and affect the flowers positioned in the lower part of the crown.

In all three times of pruning application, 'Elmar' cv. early apricot variety formed the most flowers, between 243 and 277 respectively, possibly because the trees have a longer growing period without fruit, Table 2.

The same trend was observed for fruit production, which was higher in the variant of applying the cuttings at the time of entering the dormant period in November, Table 3. The 'Elmar' cv. (with early fruit ripening) responded best to this technological work, but only in years without climatic accidents (2018, 2021), when average yields of $28-29 \mathrm{~kg} /$ tree were recorded. On the other hand, the 'Sulmona' cv. had good yields, ranging from $15-28 \mathrm{~kg}$ /apple in all years of the study, due to the fact that it flowers later which helps it to escape from the return frosts and late fogs.

In all three varieties studied, the highest average fruit weight was recorded in the variant applying cuttings at the beginning of the dormant period, $63-75 \mathrm{~g}$ (Table 4).

## Analysis of the statistical significance of the results obtained

In order to better evaluate the effect of the treatments applied to the trees of the three varieties, the results were statistically analyzed. The confidence interval chosen for the analyses was the standard 95\% ( $p=0.05$ ). Hence, the main descriptive parameters and the results of the ANOVA tests can be seen in Tables 5 to 10. As can be seen, the $p$-value in all cases is well above the $95 \%$ confidence interval ( $p>0.05$ ), leading to the conclusion that the way in which the pruning were made played a secondary role in determining the number of flowers.

In terms of fruit yield, the effect of the three pruning variants seems however to be strongly significant for 'Elmar' and 'Sulmona' cvs. ( $\mathrm{p}<0.05$ ) for all five years of experimentation, while for 'Mamaia' cv. only for 2020 and 2022 (tables 11-16).

## 4. Conclusions

Current climatic conditions in recent years, with long autumns and mild winters, are forcing a change in pruning season for this species;

The shrub rots on long second-year branches and best on May clusters that are on multi-year fruiting branches. By pruning we help the tree send the nutrient resources to the branches we want, thus we will have a higher quality and higher yield.

Post-harvest pruning causes the tree to form a large number of greedy shoots to the detriment of the fruiting branches; in addition, shoot blight occurs.

In the study, the option of pruning after harvesting the fruit was found to be the least beneficial, as the tree continues to vegetate, many greedy shoots are formed, which die back.

When the tree starts to vegetate in March, we cut back the greedy shoots but it is already late because almost all the tree's resources have been exhausted by the greedy shoots, which form an umbrella over the tree and no more light penetrates to the multiannual fruiting branches and May bunches. As a result, the tree withers and premature decline occurs.
